Abstract. The combined effects of viscous dissipation and Joule heating on steady magnetohydrodynamics (MHD) and slip flow of an electrically conducting viscous incompressible non-Newtonian Bingham fluid over a porous rotating disk in the presence of Hall and ion-slip currents is studied. An external uniform magnetic field is applied in the z-direction and the fluid is subjected to uniform suction. Numerical solutions are obtained for the governing momentum and energy equations. Results for the details of the velocity as well as temperature are shown graphically and the numerical values of the skin friction and the rate of heat transfer are entered in tables.

Key words: rotating disk, Bingham fluid, Joule heating, viscous dissipation, ion-slip currents.

1. INTRODUCTION

The rotating disk is a popular geometry for studying different fluids, both because of its simplicity and the fact that it represents a classical fluid dynamics problem. Since von Karman [1] elegantly devised a similarity transformation, which reduced the full Navier-Stokes system to a set of ordinary differential equations in a single variable, this swirling flow has received considerable interest; see, e.g., the review by Zandbergen and Dijkstra [2]. Sparrow and Cess [3] examined how the swirling flow caused by a rotating disk is affected by an axial magnetic field, whereas Mitschka and Ulbercht [4] extended von Karman analysis to non-Newtonian fluids.

The fluid that are used extensively in industrial applications are exhibiting a yield stress, that has to be exceeded before the fluid moves. As a result, such fluids cannot sustain a velocity gradient unless the magnitude of the local shear stress is
higher than this yield stress. Fluids that belong to this category include cement, drilling mud, sludge, grease, granular suspensions, aqueous foams, slurries, paints, food products, plastics and paper pulp [5]. Due to the growing use of these non-Newtonian materials in various manufacturing and processing industries, considerable efforts have been directed towards understanding their flow and heat transfer characteristics.

Many of the yield non-Newtonian fluids encountered in chemical engineering processes, are known to follow the so-called Bingham model. A Bingham fluid is a material with finite yield stress, followed by a linear curve at a finite strain rate. The yield stress concept was first introduced by Bingham and Gress [6] for a class of fluids known to be viscoplastic fluids. After their initial work, many different equations have been proposed to described the relationship between shear stress and shear rate for different viscoplastic materials (Nguyen and Boger[7]). Many authors ([8-12]) studied the flow or/and heat transfer of a Bingham fluid in different geometries.

Motion of Bingham fluid over a rotating disk has been studied earlier by several authors, e.g.([14, 15, 13]). In these previous investigations, Joule and viscous dissipations were neglected in the energy equation. To the authors’ knowledge, no study has yet considered the effects viscous dissipation and Joule heating on MHD flow of a Bingham fluid over a porous rotating disk in the presence of Hall and ion-slip currents.

A completely different extension of von Karmanos one-disk problem is the analysis of Sparrow et al. [3]. They considered the flow of a Newtonian fluid due to the rotation of a porous-surfaced disk and for that purpose replaced the conventional no-slip boundary conditions at the disk surface with a set of linear slip-flow conditions. A substantial reduction in torque then occurred as a result of surface slip. This problem was recently reconsidered by Miklavcic and Wang [20] who pointed out that the same slip-flow boundary conditions as those used by Sparrow et al. [3] also could be used for slightly rarefied gases or for flow over grooved surfaces.

The objective of this study is to present the combined effects of viscous dissipation and Joule heating on steady magnetohydrodynamics and slip flow of an electrically conducting viscous incompressible non-Newtonian Bingham fluid over a porous rotating disk. The presence of Hall and ion-slip currents taken into consideration. The governing momentum and energy equations are solve numerically by a shooting method. The inclusion of viscous and Joule heating, the suction, and the non-Newtonian fluid characteristics leads to some interesting effects on both the velocity and temperature fields.

Fig. 1 – Coordinate system for the rotating disk flow.
2. GOVERNING EQUATION

The description of the physical problem closely follows that of Rashaida et al. [14]. We use a non-rotating cylindrical polar coordinate system, \((r, \varphi, z)\) where \(z\) is the vertical axis in the cylindrical coordinates system with \(r\) and \(\varphi\) as the radial and tangential axes respectively. The homogeneous, laminar, incompressible electrically conducting Bingham fluid occupies the region \(z > 0\) with the rotating disk placed at \(z = 0\) and rotating with constant angular velocity \(\Omega\). The fluid velocity components are \((u, v, w)\) in the directions of increasing \((r, \varphi, z)\) respectively, the pressure is \(P\), the density of the fluid is \(\rho\) and \(T\) is the fluid temperature. The surface of the rotating disk is maintained at a uniform temperature \(T_w\). Far away from the wall, the free stream is kept at a constant temperature \(T_\infty\) and at constant pressure \(P_\infty\).

An external strong magnetic is applied in the \(z\)-direction and has a constant flux density \(B_0\). The magnetic Reynolds number of the flow is taken to be small enough so that the induced distortion of the applied magnetic field can be neglected. The electron-atom collision frequency is assumed to be relatively high, so that the Hall and ion-slip effects cannot be neglected [16]. Assuming the disk to be electrically non-conducting, the generalized Ohm’s law gives \(j_z = 0\) everywhere in the flow. The governing equations for this investigation are modified to include viscous and Joule heating effects with the generalized Ohm’s and Maxwell’s laws. The physical model and geometrical coordinates are shown in Fig. 1.

When the boundary layer profile is approximated, the normal strain rates can be neglected in comparison with the shear rates, and when incompressibility and rotational symmetry are taken into account, the constitutive equation of the Bingham fluid becomes [13]

\[
\tau_{rz} = \left[ \mu_0 + \frac{\tau_y}{\left( \frac{\partial u}{\partial z} \right)^2 + \left( \frac{\partial v}{\partial z} \right)^2} \right] \frac{\partial u}{\partial z}, \quad (1)
\]

\[
\tau_{r\varphi} = \left[ \mu_0 + \frac{\tau_y}{\left( \frac{\partial u}{\partial z} \right)^2 + \left( \frac{\partial v}{\partial z} \right)^2} \right] \frac{\partial v}{\partial z}. \quad (2)
\]

Then the equations governing the motion of the steady MHD flow of the Bingham fluid over a porous rotating disk can be stated as
Steady MHD and slip flow of a Bingham fluid

\[ \frac{\partial u}{\partial r} + \frac{u}{r} \frac{\partial w}{\partial z} = 0, \]  

\[ \rho \left( \frac{u}{r} \frac{\partial u}{\partial r} + \frac{v^2}{r} + w \frac{\partial u}{\partial z} \right) + \frac{\partial P}{\partial r} = \frac{\partial}{\partial r} \left( \mu \frac{\partial u}{\partial r} \right) + \frac{\partial}{\partial r} \left( \frac{\mu}{r} \frac{u}{r} \right) + \frac{\partial \tau_{rz}}{\partial z} - \frac{\sigma B_0^2}{\alpha^2 + \beta_e^2} (\alpha u - \beta_e v), \]  

\[ \rho \left( \frac{u}{r} \frac{\partial v}{\partial r} + \frac{uv}{r} + w \frac{\partial v}{\partial z} \right) = \frac{\partial}{\partial r} \left( \mu \frac{\partial v}{\partial r} \right) + \frac{\partial}{\partial r} \left( \frac{\mu}{r} \frac{v}{r} \right) + \frac{\partial \tau_{r\phi}}{\partial z} - \frac{\sigma B_0^2}{\alpha^2 + \beta_e^2} (\alpha v - \beta_e u), \]  

\[ \rho c_p \left( \frac{u}{r} \frac{\partial T}{\partial r} + w \frac{\partial T}{\partial z} \right) = \kappa \frac{\partial^2 T}{\partial z^2} + \frac{\sigma B_0^2}{\alpha^2 + \beta_e^2} (u^2 - v^2) + \mu \left[ \left( \frac{\partial u}{\partial z} \right)^2 + \left( \frac{\partial v}{\partial z} \right)^2 \right], \]

where, \( \sigma = \left( e^2 n_e t_e / m_e \right) \) is the electrical conductivity, \( e \) is the electron charge, \( t_e \) is the electron collision time, \( n_e \) is the electron number density, and \( m_e \) is the mass of the electron. \( c_p \) is the specific heat at constant pressure of the fluid, \( \alpha = 1 + \beta_e \), \( \beta_e = \omega_e^2 / \left( \left( 1 + n_e / n_a \right) K_{\text{slip}} \right) \) is the ion-slip parameter, \( n_a \) is the neutral particle number density, and \( K_{\text{slip}} \) is the friction coefficient between ions and neutral particles.

The second and third terms on the RHS of equation (6) denote the magnetic and viscous heating terms, respectively.

When the mean free path of the fluid particles is comparable to the characteristic dimensions of the flow field domain, Navier-Stokes equations break down since the assumption of continuum media fails. In the range \( 0.1 < \text{Kn} < 10 \) of Knudsen Number, the high order continuum equations, e.g. Burnett equations should be used. For the range of \( 0.1 < \text{Kn} < 10.001 \), no-slip boundary conditions can not be used and should be replaced with the following expression (Ga-el-Hak [21]):

\[ U_i = \frac{2 \psi \lambda}{\psi} \frac{\partial U_i}{\partial n}, \]  

where \( U_i \) is the target velocity, \( n \) is the normal direction to the wall, \( \psi \) is the target momentum accommodation coefficient \( \lambda \) and is the mean free path. For \( \text{Kn} < 0.001 \), the no-slip boundary condition is valid, therefore, the velocity at the surface is equal to zero. In this study the slip and the no-slip regimes of the Knudsen number that lies in the range \( 0.1 > \text{Kn} > 0 \) is considered. By using equation (7), the boundary conditions are introduced [22] as follows:
Emmanuel Osalusi, Jonathan Side, Robert Harris et al.

\[ u = \frac{2 - \xi \lambda}{\xi} \frac{\partial u}{\partial z}, \quad v = r \Omega + \frac{2 - \xi \lambda}{\xi} \frac{\partial v}{\partial z}, \quad w = W, \quad T = T_w, \quad \text{at} \quad z = 0 \]
\[ u \to 0, \quad v \to 0, \quad T \to T_w, \quad P \to P_\infty \quad \text{as} \quad z \to \infty. \quad (8) \]

3. SIMILARITY TRANSFORMATION

The solutions of the governing equations are obtained by introducing a dimensionless normal distance from the disk, \( \eta = z \left( \frac{\Omega}{\nu_0} \right)^{1/2} \), along with the von-Karman transformations,

\[ u - \Omega r F(\eta), \quad v = \Omega r G(\eta), \quad w = \left( \Omega \nu_0 \right)^{1/2} H(\eta) \]
\[ P - P_0 = 2 \mu_0 \Omega \rho(\eta) \quad \text{and} \quad T - T_0 = \left( T_w - T_0 \right) \Theta(\eta), \quad (9) \]

where \( \nu_0 \) is a uniform kinematic viscosity of the fluid. Substituting these transformations into equations (1)-(6) gives the nonlinear ordinary differential equations,

\[ H' + 2F = 0, \quad (10) \]

\[ F^* \left[ 1 + \frac{2B}{\left( F'^2 + G'^2 \right)^{1/2}} - \frac{2BF'^2}{\left( F'^2 + G'^2 \right)^{3/2}} \right] - \frac{2BF'G'^*}{\left( F'^2 + G'^2 \right)^{3/2}} - \left[ F^2 - G^2 + F'H \right] - \left[ \frac{M}{\left( \alpha^2 + \beta_e^2 \right)} \left( \alpha F - \beta_e G \right) \right] = 0, \quad (11) \]

\[ G^* \left[ 1 + \frac{2B}{\left( F'^2 + G'^2 \right)^{1/2}} - \frac{2BG'^2}{\left( F'^2 + G'^2 \right)^{3/2}} \right] - \frac{2BF'G'^*}{\left( F'^2 + G'^2 \right)^{3/2}} - \left[ 2F^2 G + HG' \right] - \left[ \frac{M}{\left( \alpha^2 + \beta_e^2 \right)} \left( \alpha G - \beta_e F \right) \right] = 0, \quad (12) \]

\[ \frac{\theta^*}{\Pr} - H\theta' + \frac{EcM}{\alpha^2 + \beta_e^2} \left( F^2 + G^2 \right) + Ec \left( 1 + 2B \right) \left( F'^2 + G'^2 \right) = 0, \quad (13) \]
where: \( B = \tau_y / \left( 2\rho \Omega r (\nu_0 \Omega)^{1/2} \right) \) is a Bingham number \([13]\), \( \nu_0 = \mu_0 / \rho \) is the kinematic viscosity of the plastic fluid, \( \text{Pr} = \mu_0 c_p / \kappa \) is the Prandtl number, \( M = \sigma B_0^2 / (\rho \Omega) \) is the magnetic interaction parameter that represents the ratio of the magnetic force to the fluid inertial, \( \text{Ec} = (r^2 \Omega^2) / \left[ (T_w - T_0) c_p \right] \) is the Eckert number. A prime symbol denotes a derivative with respect to \( \eta \). The transformed boundary conditions are given by:

\[
F = \gamma F', \quad G = 1 + \gamma G', \quad H = W, \quad \theta = 1 \quad \text{at} \quad \eta = 0 \quad (14)
\]

\[
F = G = \theta = p = 0, \quad \text{at} \quad \eta \to \infty, \quad (15)
\]

where \( \gamma = \left[ (2 - \xi) \lambda \Omega^{1/2} \right] / \xi \Omega^{1/2} \) is the slip factor, \( W = w / \sqrt{\nu_0 \Omega} \) represents a uniform suction \((W < 0)\) or injection \((W > 0)\) at the surface. The boundary conditions \((15)\) imply that both the radial \((F)\), the tangential \((G)\), temperature and pressure vanish sufficiently far away from the rotating disk, whereas the axial velocity component \((H)\) is anticipated to approach a yet unknown asymptotic limit for sufficiently large \( \eta \)-values.

The skin friction coefficients and the rate of heat transfer to the surface are given by:

\[
\tau_i = \mu \left[ \frac{\partial v}{\partial z} + \frac{1}{r} \frac{\partial w}{\partial \phi} \right]_{\eta=0} = \mu_0 \left[ 1 + \frac{2B}{(F'(0)^2 + G'(0)^2)^{1/2}} \right] \text{Re}^{1/2} \Omega G'(0),
\]

and

\[
\tau_r = \mu \left[ \frac{\partial u}{\partial z} + \frac{1}{r} \frac{\partial w}{\partial \phi} \right]_{\eta=0} = \mu_0 \left[ 1 + \frac{2B}{(F'(0)^2 + G'(0)^2)^{1/2}} \right] \text{Re}^{1/2} \Omega F'(0),
\]

Hence the tangential and radial skin-frictions are respectively given by

\[
\mu_0 \left[ 1 + \frac{2B\mu_0}{(F'(0)^2 + G'(0)^2)^{1/2}} \right]^{-1} \text{Re}^{1/2} \mu C_k = G'(0), \quad (16)
\]

and
Fourier’s law

\[ q = -\kappa \left( \frac{\partial T}{\partial z} \right)_{z=0} = -\kappa \left( \frac{\Omega}{\nu} \right)^{1/2} \theta'(0), \]

is used to calculate the rate of heat transfer from the disk surface to the fluid. The Nusselt number \( \text{Nu} \) is obtained as

\[ R^{-1/2} \text{Nu} = -\theta'(0), \]

where \( R = \Omega r^2 / \nu \) is the rotational Reynolds number and \( \nu = \mu_0 / \rho \) is the kinematic viscosity of the plastic fluid.

4. METHOD OF SOLUTION

The systems of nonlinear ordinary differential equations (10)-(13) is solved under the condition given in (15) for the three components of the flow velocity and temperature distribution, using the shooting method ([18, 19]). The resulting system of first order equations has to be solved in the infinite domain \( 0 < \eta < 1 \). A finite domain in the \( \eta \)-direction can be used instead with \( \eta \) chosen large enough to ensure that the solutions are not affected by imposing the asymptotic conditions at a finite distance. The dependence of the results from the length of the finite domain was ensured and successfully checked by various trial and error numerical experimentations. Table 1 demonstrates these numerical experiments in evaluating the axial flow at infinity \( H_i \) for various values of the Hall parameters \( \beta_e \) and using a finite distances \( \eta_{\infty} \). As clear from the table that \( \eta_{\infty} = 51 \) is adequate and therefore, computations are carried out based on this value.

5. NUMERICAL RESULTS AND DISCUSSION

For numerical computations, we took \( \text{Pr} = 0.72 \), which is the value of Prandtl number for air. We have confined our analysis to the case when we have suction velocity only, that is, when \( W < 0 \). Table 2 displays the numerical results for \( F'(0), G'(0) \) and \( -\theta'(0) \) for different values of \( \gamma, B, M, Ec, \beta_e \) and \( \beta_f \). Inspection of Table 2 reveals that a moderate increase in the value of the slip factor
may lead to a gradual monotonic decrease in the radial \( F'(0) \) and tangential \( G'(0) \) skin-friction coefficient, while it increases the rate of heat transfer \( \theta'(0) \) coefficient.

</table>

The values are calculated numerically for various combinations of parameters, demonstrating the effect of different conditions on the fluid behavior described by the Bingham model.
Table 2 reveals that a moderate increase in the value of the $B$ may lead to a gradual monotonic decrease in the radial $F'(0)$, tangential $-G'(0)$ skin-friction and the rate of heat transfer $-\theta'(0)$ coefficient respectively. In Table 2 we noticed that an increase in $M$ increases $F'(0)$ but decreases both $-G'(0)$ and $-\theta'(0)$. This is due to the fact that magnetic field reduces the radial $F$ (Fig. 2a), but increases the tangential velocity $G$ (Fig. 2b) and temperature $\theta$ (Fig. 2d). Further, we observe that radial skin friction $F'(0)$, tangential skin friction $-G'(0)$ and the rate of heat transfer $-\theta'(0)$ decrease with Ec. Also, an increase in the values of Hall parameter $\beta_e$ increases both the shear stress in the radial $F'(0)$ direction and the rate of heat transfer $-\theta'(0)$ coefficient while increase in the value of $\beta_e$ decreases shear stress in the tangential $-G'(0)$ direction. Table 2 reveals that as ion-slip parameter $\beta_i$ increases, the radial skin friction $F'(0)$ decreases with an increase in both tangential skin friction $-G'(0)$ and rate of heat transfer coefficient $-\theta'(0)$ increases respectively.

The shear-driven flow ($G$) in the tangential direction in Fig. 2b is gradually reduced with increasing values of $\gamma$. The centrifugal force associated with this circular motion causes the outward radial flow ($F$), which is correspondingly reduced with decreasing slip coefficient close to the disk surface. The radial outflow $F$ is compensated by an axial inflow $H$ towards the rotating disk, in accordance with the mass concentration equation (10). The gradual reduction of the peak in the $F$-profiles in Fig. 2a with decreasing values of $\gamma$ is reflected in the distributions of the axial velocity component in Fig. 2c. The distinct inflection point in the $H$-profiles for the highest values of $\gamma$ seems to gradually disappear with increasing slip. This is a consequence of the direct coupling between the radial and axial velocity components through the continuity constraint (10). The reduction of the radial velocity $F(\eta)$ with decreasing $\gamma$ automatically gives rise to a reduced axial inflow since

$$-H(\infty) = \int_0^\infty F \, d\eta.$$  \hspace{1cm} (20)

Figure 2d shows the temperature profile. A general decrease in temperature profile is observed with maximum at the disk surface and minimum far away from the disk. The magnitude of the temperature profiles decreases slightly with increase in slip coefficient.

Similarity solutions for three velocity components (radial, tangential and axial) and the temperature are presented in Figures 3a-3d for values of the
Bingham number $B$ in the range of 1 to 3. Figure 2a depicts the representative radial velocity $F$ distributions. It is noted that $F$ decreases as the strength of Bingham number increases. Since the radial velocity is zero at both the surface of the disk and in the far field, there must be a maximum value somewhere in between. The profile of the radial velocity $F$ becomes flatter as the value of $B$ is increased, i.e. the maximum velocity decreases, and its location moves slightly further from the disk. For $B > 0$, the radial outflow must carry away the incoming axial flow with an apparent viscosity now consisting of two parts, i.e., the Bingham plastic viscosity and the yield stress. Thus, the level of the radial velocity $-H$ component decreases (Fig. 3c) with increasing $B$ and also persists a longer distance from the disk before it vanishes. Fig. 3b shows the tangential velocity $G$ profiles. It is readily seen from Fig. 3b that $G$ increases with $B$. The temperature $\theta$ profiles is shown in Fig. 3d. We noticed that an increase in Bingham number $B$ increases the temperature $\theta$. This is due to the fact that increase in Bingham number increases the yield stress and in turn increases the viscous dissipation of the fluid.

Figures 4a–4d show typical profiles for the fluid radial velocity $F$, tangential velocity $G$, axial velocity $-H$ and temperature $\theta$ for different values of the magnetic parameter $M$, respectively. Due to the damping effect of the magnetic field, increases in the values of $M$ have a tendency to slow the motion of the fluid in radial $F$, tangential $G$ and axial $-H$ directions and make it warmer as it moves over the disk causing the temperature $\theta$ to increase.

Figures 5a–5d show the $F$, $G$, $-H$ and $\theta$ profiles for various values of $\beta_e$ between 0 and 0.3. We observe that radial velocity $F$, tangential velocity $G$ and axial velocity $-H$ increase while the temperature $\theta$ decreases as the Hall current parameter $\beta_e$ increases since the magnetic damping on $F$, $G$ and $-H$ decreases as $\beta_e$ increases coupled with the fact that magnetic field has a propelling effect on $F$, $G$ and $-H$.

Figures 6a–6d describe the behaviour of $F$, $G$ and $\theta$ with changes in the values of the ion-slip parameter $\beta_i$. From Figs. 6a–6d, it is clear that an increase in the ion-slip parameter $\beta_i$ leads to a decrease in the radial velocity $F$, tangential velocity $G$, axial velocity $-H$ and temperature $\theta$. In general, it is noted that, the effect of Hall parameter $\beta_e$ on the flow and thermal fields is more notable than that of ion-slip parameter $\beta_i$. This is attributed to the fact that the diffusion velocity of the electrons is much larger than that of ions.

Figure 7 illustrates the temperature $\theta$ profiles for various values of $E_c$ between 0 and 0.3. It is noticed that temperature $\theta$ increases with Eckert number $E_c$. The rise in the temperature $\theta$ is due to the heat created by the increase in viscous dissipation and compression work ($E_c \neq 0$).

6. CONCLUSIONS

In this study we have examined the effects of viscous dissipation and Joule heating on steady hydromagnetic and slip flow of a Bingham fluid over a porous rotating disk in the presence of Hall and ion-slip currents. Employing von Karman similarity transformation technique, the governing equations are transformed into ordinary differential equations and solve numerically by the shooting method. We present results to illustrate the flow characteristics for the velocity and temperature fields as well as the skin friction and rate of heat transfer, and show how the flow fields are influenced by the material parameters of the flow problem. We can conclude from our results that slip factor $\gamma$ and Bingham number $B$ has significant effects on the flow behaviour. We noticed that slip factor decreases radial, tangential and axial velocity components while it increases the temperature. Also, Bingham number decreases the magnitude of the radial and axial velocity components, skin frictions and rate of heat transfer, and increases the magnitude of the tangential velocity component and temperature. We also discovered that an increase in Hall parameter $\beta_{e}$, ion-slip parameter $\beta_{i}$ decrease the temperature profiles while an increase in magnetic parameter and Eckert number decrease the rate of heat transfer coefficient.
